Atomic Structure and the Periodic Table

Understanding atomic structure and the periodic table is fundamental to AQA AS Chemistry Unit 1. This section focuses on the arrangement of subatomic particles, isotopes, and electronic configurations. It also explores periodic trends that influence element properties such as atomic radius, ionization energy, and electronegativity.

Subatomic Particles

Atoms consist of protons, neutrons, and electrons. Protons carry a positive charge and reside in the nucleus, neutrons are neutral particles also in the nucleus, and electrons are negatively charged particles orbiting the nucleus in defined energy levels or shells. The atomic number corresponds to the number of protons,

which determines the element's identity, while the mass number is the sum of protons and neutrons.

Isotopes

Isotopes are atoms of the same element with different numbers of neutrons. They have identical chemical properties but differing physical properties, such as mass. The relative atomic mass (A_r) of an element is the weighted average of the masses of its naturally occurring isotopes, taking into account their abundance.

Electronic Configuration and Periodicity

The arrangement of electrons in shells follows the 2,8,8 rule for the first 20 elements, with electrons occupying orbitals in increasing energy levels. Electronic configurations explain periodic trends such as ionization energy and atomic radius. The periodic table is organized into groups and periods that reflect these trends.

- Group 1 elements have one electron in their outer shell, making them highly reactive.
- Transition metals exhibit variable oxidation states due to their d-electrons.
- Period 2 elements show trends in electronegativity and ionization energy across the period.

Chemical Bonding and Structure

Chemical bonding describes the forces holding atoms together in molecules and compounds. This section covers ionic, covalent, and metallic bonding, alongside the structures formed by these bonds and their properties. Understanding bonding is crucial for predicting molecular geometry, polarity, and physical characteristics of substances.

Ionic Bonding

Ionic bonding occurs between metals and non-metals, involving the transfer of electrons to form oppositely charged ions. These ions arrange themselves in a lattice structure, resulting in high melting and boiling points due to strong electrostatic forces. Ionic compounds conduct electricity when molten or dissolved in water.

Covalent Bonding

Covalent bonds involve the sharing of electron pairs between non-metal atoms. Simple molecular substances have low melting points due to weak intermolecular forces, whereas giant covalent structures like diamond and graphite have high melting points due to strong covalent bonds. The shape of molecules is explained by the VSEPR theory, which accounts for electron pair repulsions.

Metallic Bonding

Metallic bonding features a lattice of positive metal ions surrounded by a sea of delocalized electrons. This bonding accounts for properties such as electrical conductivity, malleability, and high melting points. The strength of metallic bonds varies depending on the number of delocalized electrons and the size of metal ions.

- Bond polarity arises from differences in electronegativity between bonded atoms.
- Intermolecular forces include London dispersion forces, dipole-dipole interactions, and hydrogen bonding.
- Molecular geometry influences physical and chemical properties.

Quantitative Chemistry

Quantitative chemistry focuses on the measurement of substances and the calculations related to chemical reactions. This section encompasses moles, molar mass, empirical and molecular formulas, and concentration calculations. Mastery of these concepts is vital for accurate stoichiometric analysis.

The Mole Concept

The mole is the unit for amount of substance, defined by Avogadro's number (6.02×10^{23} particles). Molar mass is the mass of one mole of a substance, expressed in grams per mole. Calculations involving moles enable the determination of reactant and product quantities in chemical reactions.

Empirical and Molecular Formulas

Empirical formulas represent the simplest whole-number ratio of atoms in a compound, while molecular formulas indicate the actual number of atoms. Determining these formulas requires experimental data such

as percentage composition and molar mass.

Concentration and Solutions

Concentration measures the amount of solute in a given volume of solution, typically expressed in moles per liter (mol/L). Calculations involving concentration, volume, and moles are essential for preparing solutions and analyzing reactions in solution.

- Calculating reacting masses using balanced equations.
- Limiting reactant and percentage yield concepts.
- Gas volume calculations using molar volume at room temperature and pressure ($24 \text{ dm}^3/\text{mol}$).

Energetics

Energetics examines the energy changes during chemical reactions. This section explains exothermic and endothermic reactions, bond enthalpies, and Hess's law. Understanding energetics is key to predicting reaction feasibility and stability.

Exothermic and Endothermic Reactions

Exothermic reactions release energy to the surroundings, resulting in a temperature increase, whereas endothermic reactions absorb energy, causing a temperature decrease. These energy changes can be represented on enthalpy profile diagrams.

Bond Enthalpy

Bond enthalpy is the energy required to break one mole of a particular bond in a gaseous molecule. Calculating overall enthalpy changes involves summing the bond enthalpies of bonds broken and bonds formed in a reaction.

Hess's Law

Hess's law states that the total enthalpy change for a reaction is the same regardless of the pathway taken.

This principle allows indirect calculation of enthalpy changes using known reaction steps.

- Standard enthalpy changes measured under standard conditions (298 K, 1 atm).
- Practical applications in calorimetry experiments.
- Using enthalpy cycles to find enthalpy changes not easily measured directly.

Kinetics

Kinetics studies the rates of chemical reactions and the factors affecting them. This section covers rate equations, collision theory, activation energy, and catalysts. Understanding kinetics aids in controlling reaction conditions to optimize product yield.

Reaction Rate

Reaction rate is the change in concentration of reactants or products per unit time. It can be measured by monitoring changes in mass, volume, or color intensity over time. The rate depends on factors such as concentration, temperature, surface area, and catalysts.

Collision Theory

According to collision theory, reactions occur when particles collide with sufficient energy and proper orientation. The activation energy is the minimum energy required for successful collisions to form products.

Catalysts

Catalysts increase reaction rates by providing an alternative pathway with lower activation energy. They are not consumed in the reaction and can be homogeneous or heterogeneous. Catalysts are crucial in industrial processes to improve efficiency.

- Effect of temperature on reaction rates explained by the Arrhenius equation.
- Graphical methods for determining reaction order and rate constants.

- Practical examples of catalysts in chemical industry and everyday life.

Chemical Equilibria and Le Chatelier's Principle

Chemical equilibria involve reactions that are reversible and reach a state where the forward and reverse reaction rates are equal. This section explains equilibrium position, dynamic equilibrium, and how changes in conditions affect equilibrium according to Le Chatelier's principle.

Dynamic Equilibrium

At dynamic equilibrium, concentrations of reactants and products remain constant over time, although both reactions continue to occur. This state is characteristic of reversible reactions in closed systems.

Le Chatelier's Principle

This principle predicts how an equilibrium system responds to changes in concentration, pressure, or temperature. The system shifts to counteract the imposed change, restoring equilibrium.

Equilibrium Constant (K_c)

The equilibrium constant expresses the ratio of product concentrations to reactant concentrations at equilibrium, raised to the power of their stoichiometric coefficients. It indicates the extent to which a reaction proceeds and is temperature-dependent.

- Impact of increasing concentration shifts equilibrium towards the opposite side.
- Effect of pressure changes on equilibria involving gases.
- Temperature effects on endothermic and exothermic reactions altering K_c values.
